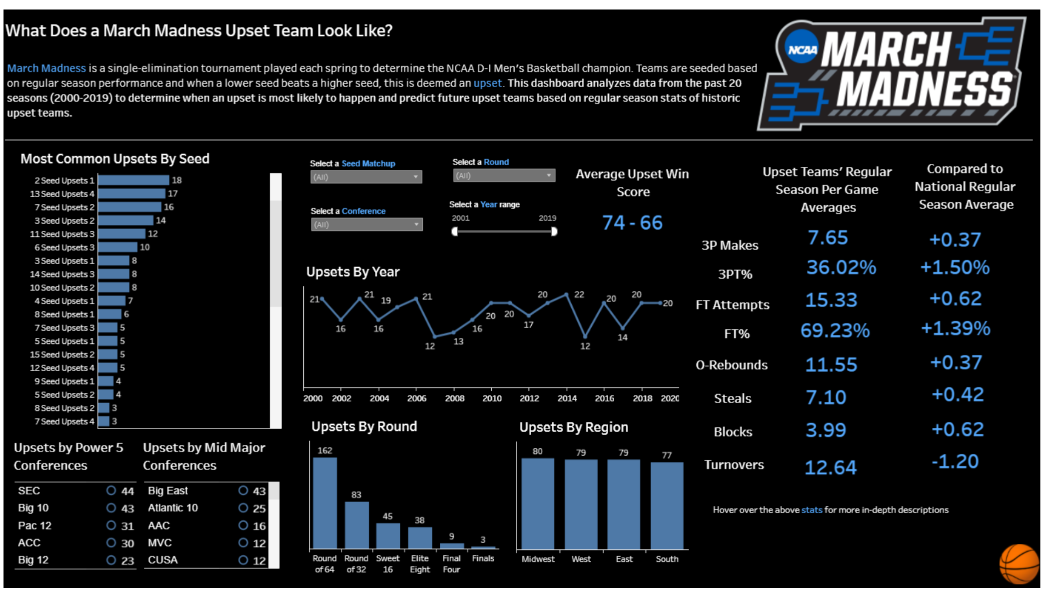
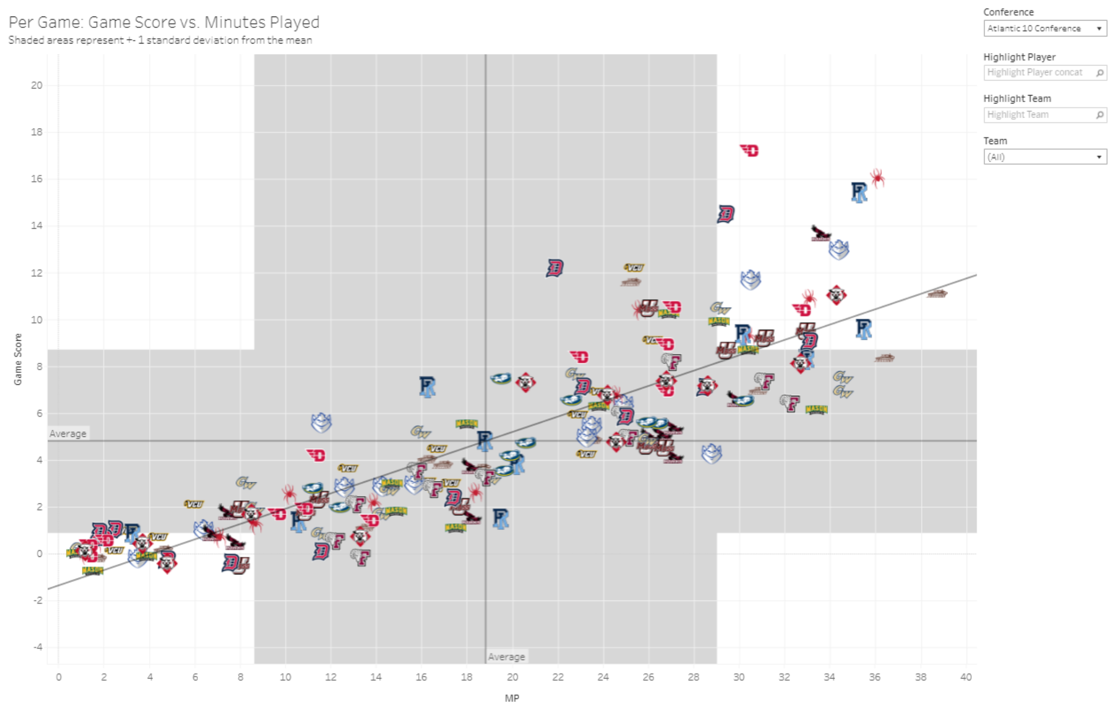
Inspiration and Overview

For our project, we chose to look at March Madness. Every year around this time the sports world is abuzz about March Madness. Underdogs vs Giants, last second buzzer beaters, and legends that form from each tournament. And with every tournament, comes the tournament bracket challenge! No one has ever created the perfect bracket, so we thought it would be fun to create a machine learning model to help us better predict the men's tournament outcome and each matchup along the way.

We began to build our application around data collected for the 2021 season. Our goal was then to test the strength of our model against past tournaments going all the way back to 2016. Additionally, since the tournament didn't occur in 2020 we would make predictions on who would have been crowned the champion of that year. We decided to power our Flask app using Python, HTML/CSS, Javascript and Tableau.

We found some really cool Tableau visualizations as well as a Kaggle challenge that happens yearly that inspired us on how we would approach diving into the world of March Madness.





In our analysis of March Madness, we used 8 datasets. 6 of the datasets were used for Tableau visualizations while the others were used for machine learning. The 6 that were used for Tableau visualizations consisted of team names, detailed statistics in regular season play as well as tournament play, coach names, conferences by season and team, and conference names.

Questions to be asked of our data include: (i) Who will win the 2021 NCAA Tournament? (ii) How many points will they score? (iii) Who would have won the 2020 NCAA Tournament had it not been canceled due to COVID 19?

Data & Modeling Approach

Our original datasets required some data cleansing. The detailed statistics datasets, both regular season play and tournament play, had winning team ID and losing team ID that needed to be converted into a singular team ID for Tableau joining. It also had all of it's statistics listed by winning team and losing team. This wouldn't work for visualizations/Tableau unions so the data had to be broken out into new lines with singular titled statistics as well as additional columns to one-hot-encode wins/losses as well as regular/tournament play. Then it had to be joined back together creating a new dataset with all statistics for both regular season and tournament play. From there we let the other 4 datasets from Kaggle be joined to the newly created stats dataset to allow for things like team names, coach names, and conference names to be included in our Tableau visualizations.

For the datasets used in Machine learning, we discovered Ken Pomeroy who collects the most advanced college basketball analytics in the industry. This is also known as “KenPom data”. The KenPom data is offense/defense metrics per 100 possessions per team.

2021 Pomeroy College Basketball Ratings

We also found a large dataset of regular season data from Kaggle spanning from present day to 1985. This was merged with our KenPom data on “Winning Team ID” and “Losing Team ID”. This gave us each winning and losing teams full season KenPom metrics. We cleaned the data and removed all “made” baskets so our model wouldn’t just add up previous made baskets and build predictions off known points scored.

3	4	Michigan 1	B10	22-4	29.29	118.6	7	89.3	11	66.9	...	0.029	110	15.
4	5	Illinois 1	B10	24-7	28.87	117.6	9	88.8	7	70.5	...	0.022	129	18.

We trained our model off our cleaned data to predict possible points scored. Our logic was the model would find “X” amount of points scored as well as “Y” amount of points allowed with the KenPom metrics. We would add X & Y and divide by two and that would give us our average of possible points.

We decided on the Gradient Boost model because the out of sample r2 was the best fit available. The linear regression model we ran overfit the data as the r2 value was 1.000. When we had a trained model, we grouped our data game by game on “Team ID” and took an average of that season. Our KenPom metrics would be the same and the game by game data would change since we have our season averages.

Results of Data Analysis

(i) Who will win the 2021 NCAA Tournament? How many points will they Score?

- Iowa Wins against Illinois: 80 - 76

(ii) Who would have won the 2020 NCAA Tournament had it not been canceled due to COVID 19?

- Michigan State Wins against BYU: 76 - 74

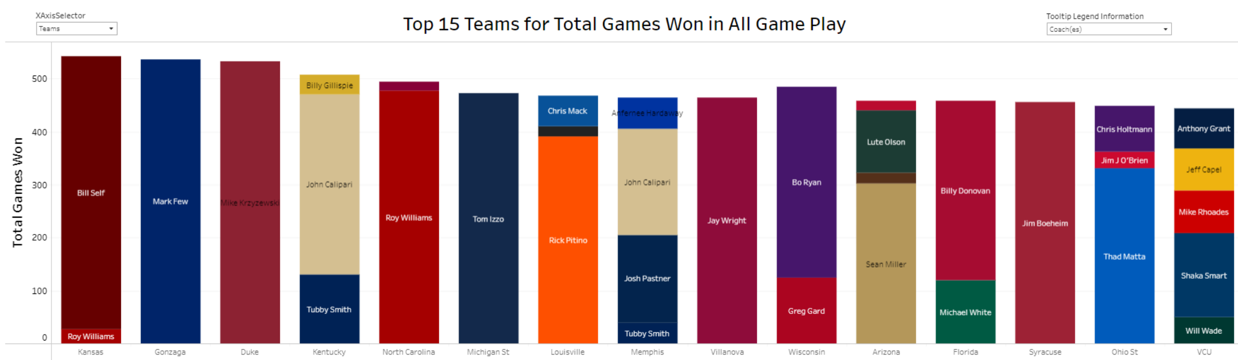
(iii) Model Results

- The model accurately predicted 23 out of 32 (72%) first round matchups correctly for the 2021 NCAA Tournament
- Since the model was finalized after the first and second round of the tournament had already been completed, we entered the future predictions into ESPN’s 2nd chance tournament challenge. The 2nd chance tournament challenge includes the 16 remaining teams in the NCAA tournament and their matchups. As of 3/28, the model’s “predicted” brackets sits in the 91th percentile and has correctly predicted all but 2 outcomes.

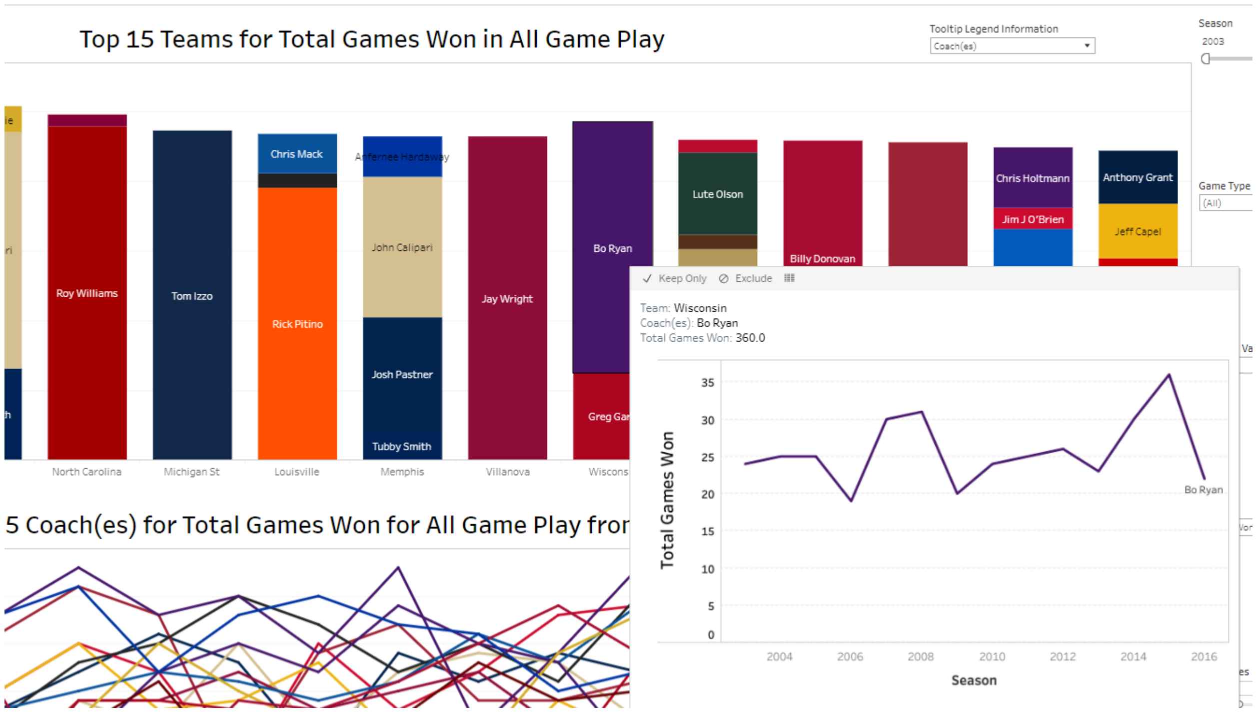
(iv) Exploring the Tableau visualizations

The main Tableau visualization is the Stats Dashboard. This visualization allows the user to manipulate season range, type of game, statistic viewed, the value of the statistic whether it be total or average, and the amount of top chosen values to view. From there the bar chart and line chart differ slightly.

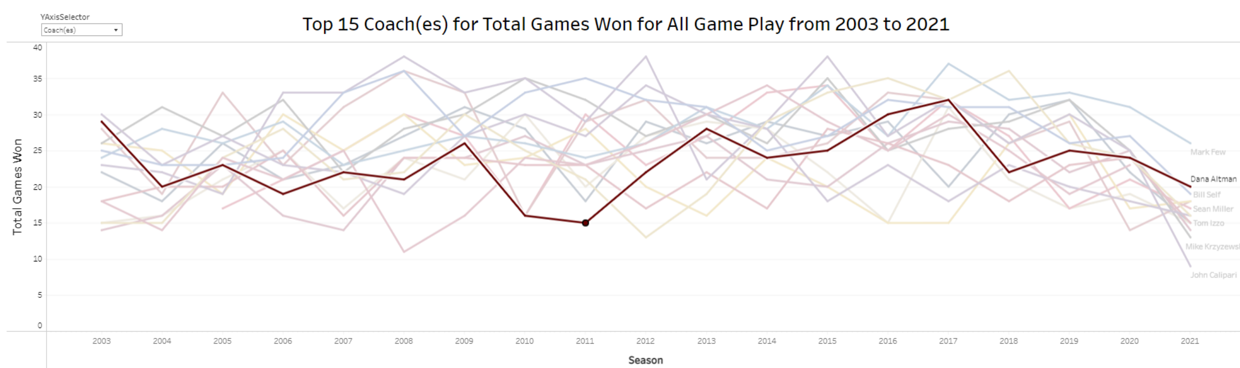
The bar chart has two additional drop downs to use: XAxisSelector and Tooltip Legend Information. The XAxisSelector allows the user to choose what value they want to see on the x axis, whether it be teams, coaches, or conferences. The Tooltip Legend Information drop down allows the user to choose what they will see in the tooltip as well as what coloring will be viewed in the visualization itself. An example could be the user selects teams as their x axis, and coaches as their tooltip legend information allowing them to see the teams as the main point of interest, but then broken out into sections of color identifying the coaches that contributed to that team.



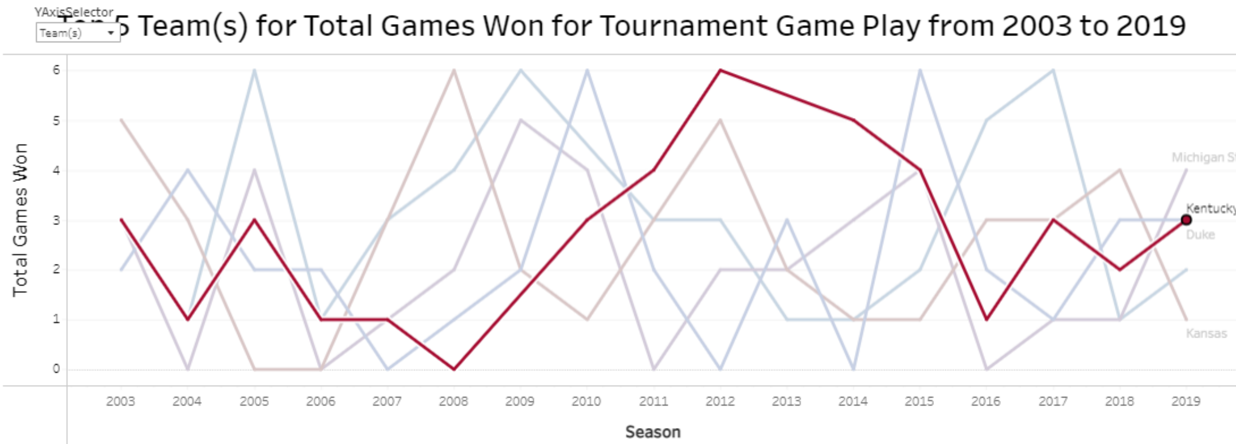
Additionally, if the user hovered over a specific coach segment of a team's bar, the tooltip that pops up will display the coach's contribution over time for the chosen stat viewed.



The line chart has one additional drop down to use, the YAxisSelector. Similar to the XAxisSelector from the bar chart visualization, the YAxisSelector lets the user select which value they want to see on the y axis, whether it be teams, coaches, or conferences.

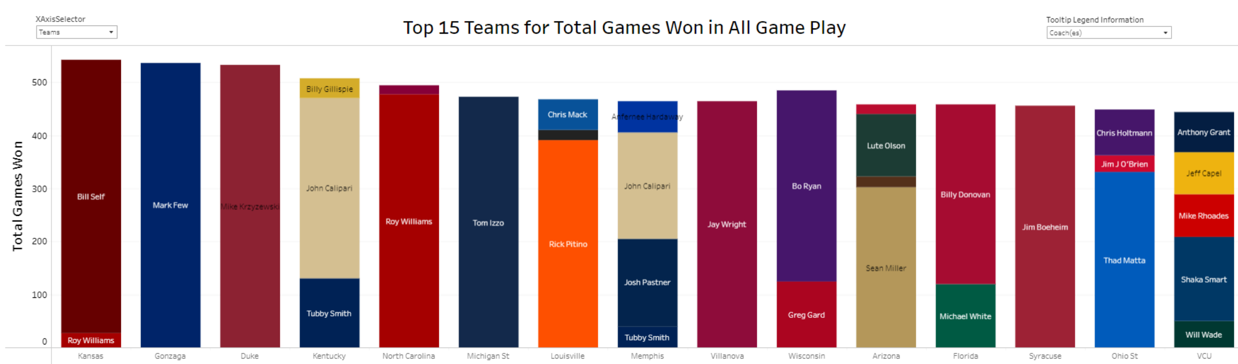


In exploring the data, we made some interesting findings! For example, did you know that while Kentucky won the 2012 NCAA tournament, they didn't even make the tournament in 2013! We found this by discovering a slight limitation to the line chart visualization. When filtered to tournament wins only by team, you'll see that Kentucky has a smooth down curve from 2012 to 2014 making it look like they had 5.5 tournament wins in 2013.



This would be impossible! Further research provided evidence showing that they didn't even make the tournament in 2013, but followed back up in 2014 by nearly winning it all once more.

We also noticed another slight limitation that led us to another discovery. The bar chart works exactly as it should, however you'll notice in the screenshot below, Wisconsin shows that it had 485 wins from 2003 to 2021, when in fact it only had 463. This is because during the 2016 season Wisconsin had 2 head coaches. Bo Ryan started out the season leading Wisconsin to a 7-5 record only to retire in December due to allegations of him having an affair. The job was given to Greg Gard mid season because of this. As a result, you'll see the 2016 season wins factored in twice, once for Bo Ryan and another for Greg Gard, overstating the total wins during the 2016 season for Wisconsin.



Limitations/Bias

The model uses known KenPom data to make predictions. While historical data is helpful, the model would be limited in predicting 2022 outcomes. It is possible to calculate KenPom data throughout the season, or to use a "rolling" number of games to determine a team's current KenPom statistics. However, given how much a college basketball team changes season-to-season, the model has been limited to use season ending KenPom statistics.

There are components that regress to the season averages for points scored. While that is expected, the model does not capture “blow out wins” or “blow out losses.” As in some other scoring prediction models, the “point-spread” of each game (amount of points the favored team is projected to win by based on probability) was not factored into our model.
The model may be biased to teams with a higher than average “Tempo.” i.e. fast-paced or high scoring teams seem to outperform actual outcomes when run through the model regardless of the caliber defense they play against. By back-testing the model against actual results in previous tournament years we found that high tempo teams were often predicted to score at or above their season average points against “stronger” teams. The actual result showed many of these games were 20+ point losses as opposed to close, high scoring games.

Future Work Recommendations

Currently, the scoring prediction model can be described as limited and complex. While it does an average job of predicting outcomes, there is plenty of room for improvement. Future work may include pulling in additional data from previous years (pre-2016) as those were not included in our initial analysis.

Creating a bracket that would auto-complete based on the winners of each individual matchup. Additionally, historically “seed” performance probability could be added to the model to refine predictions for first round matchups. For example, a #1 seed has lost to a #16 seed only 1 out of 144 times (0.69%) in the history of the NCAA tournament. Our model does not capture that data and views every game as “equal.”

Adding individual player information to the game-by-game information to train the model to capture the “importance” of individuals on a specific team. This might give some insight to what people can expect if a “star player” gets injured before a future matchup.

Lastly, the ideal goal for future work would be to further refine features in order to reduce model complexity and increase explainability.
